Chapter 8

PROGRAM DEVELOPMENT

in the Unix Programming Environment

The UNIX system was originally meant as a program development environment. In this chapter we'll talk about some of the tools that are particularly suited for developing programs. Our vehicle is a substantial program, an interpreter for a programming language comparable in power to BASIC. We chose to implement a language because it's representative of problems encountered in large programs. Furthermore, many programs can profitably be viewed as languages that convert a systematic input into a sequence of actions and outputs, so we want to illustrate the language development tools.

In this chapter, we will cover specific lessons about

- `yacc`, a parser generator, a program that generates a parser from a grammatical description of a language;
- `make`, a program for specifying and controlling the process by which a complicated program is compiled;
- `lex`, a program analogous to `yacc`, for making lexical analyzers.

We also want to convey some notions of how to go about such a project—the importance of starting with something small and letting it grow; language evolution; and the use of tools.

We will describe the implementation of the language in six stages, each of which would be useful even if the development went no further. These stages closely parallel the way that we actually wrote the program.

(1) A four-function calculator, providing `+ - * /` and parentheses, that operates on floating point numbers. One expression is typed on each line; its value is printed immediately.

(2) Variables with names `a` through `z`. This version also has unary minus and some defenses against errors.

(3) Arbitrarily-long variable names, built-in functions for `sin`, `exp`, etc., useful constants like π (spelled `PI` because of typographic limitations), and an exponentiation operator.

(4) A change in internals: code is generated for each statement and subsequently interpreted, rather than being evaluated on the fly. No new features are added, but it leads to (5).

(5) Control flow: `if-else` and `while`, statement grouping with `{` and `}`, and relational operators like `>`, `<=`, etc.

(6) Recursive functions and procedures, with arguments. We also added statements for input and for output of strings as well as numbers.

The resulting language is described in Chapter 9, where it serves as the main example in our presentation of the UNIX document preparation software. Appendix 2 is the reference manual.

This is a very long chapter, because there's a lot of detail involved in getting a non-trivial program written correctly, let alone presented. We are assuming that you understand C, and that you have a copy of the *Unix Programmer's Manual,* Volume 2, close at hand, since we simply don't have space to explain every nuance. Hang in, and be prepared to read the chapter a couple of times. We have also included all of the code for the final version in Appendix 3, so you can see more easily how the pieces fit together.

By the way, we wasted a lot of time debating names for this language but never came up with anything satisfactory. We settled on `hoc`, which stands for "high-order calculator." The versions are thus `hoc1`, `hoc2`, etc.

Stage 1: A four-function calculator

This section describes the implementation of `hoc1`, a program that provides about the same capabilities as a minimal pocket calculator. It has only four functions: `+`, `-`, `*`, and `/`, but it does have parentheses that can be nested arbirarily deeply, which few pocket calculators provide. If you type an expression followed by RETURN, the anwer will be printed on the next line:

```
$ hoc1
4*3*2
        24
(1+2) * (3+4)
        21
1/2
        0.5
355/113
        3.1415929
-3-4
hoc1: syntax error near line 4      It doesn't have unary minus yet
$
```

Grammars. Ever since Backus-Naur Form was developed for Algol, languages have been described by formal grammars. The grammar for `hoc1` is small and simple in its abstract representation:

```
list:  expr \n
       list expr \n
expr:  NUMBER
       expr + expr
       expr - expr
       expr * expr
       expr / expr
       ( expr )
```

In other words, a `list` is a sequence of expressions, each followed by a newline. An expression is a number, or a pair of expressions joined by an operator, or a pharenthesized expression.

This is not complete. Among other things, it does not specify the normal precedence and associativity of the operators, nor does it attach a meaning to any construct. And although `list` is defined in terms of `expr`, and `expr` is defined in terms of `NUMBER`, `NUMBER` itself is nowhere defined. These details have to be filled in to go from a sketch of the language to a working program.

Overview of yacc. `yacc` is a *parser generator*,† that is, a program for converting a grammatical specification of a language like the one above into a parser that will parse statements in the language. `yacc` provides a way to associate meanings with the components of the grammar in such a way that as the parsing takes place, the meaning can be "evaluated" as well. The stages in using `yacc` are the following.

First, a grammar is written, like the one above, but more precise. This specifies the syntax of the language. `yacc` can be used at this stage to warn of errors and ambiguities in the grammar.

Second, each rule or *production* of the grammar can be augmented with an *action*—a statement of what to do when an instance of that grammatical form is found in a program being parsed. The "what to do" part is written in C, with conventions for connecting the grammar to the C code. This defines the semantics of the language.

Third, a *lexical scanner* is needed, which will read the input being parsed and break it up into meaningful chunks for the parser. A `NUMBER` is an example of a lexical chunk that is several characters long; single-character operators like `+` and `*` are also chunks. A lexical chunk is called a *token*.

Finally, a controlling routine is needed, to call the parser that `yacc` built.

`yacc` proceses the grammar and the semantic actions into a parsing function, named `yyparse`, and writes it out as a file of C code. If `yacc` finds no errors, the parser, the lexical analyzer, and the control routines can be compiled, perhaps linked with other C routines, and executed. The operation of this program is to call repeatedly upon the lexical analyzer for tokens, recognize the grammatical (syntactic) structure in the input, and perform the semantic actions as each grammatical rule is recognized. The entry to the lexical analyzer must be named

† `yacc` stands for "yet another compiler-compiler," a comment by its creator, Steve Johnson, on the number of such programs extant at the time it was being developed (around 1972). `yacc` is one of a handful that have flourished.

yylex, since that is the function that yyparse calls each time it wants another token. (All names used by yacc start with y.)

To be somewhat more precise, the input to yacc takes this form:

```
%{
C statements like #include, declarations, etc. This section is optional
%}
yacc declarations: lexical tokens, grammar variables,
    precedence and associativity information
%%
grammar rules and actions
%%
more C statements (optional):
main() { ...; yyparse(); ... }
yylex() { ... }
...
```

This is processed by yacc and the result is written into a file called y.tab.c, whose layout is like this:

```
C statements from between %{ and %}, if any
C statements from after second %%, if any:
main() { ...; yyparse(); ...  }
yylex() { ...  }
...
yyparse() { parser, which calls yylex() }
```

It is typical of the UNIX approach that yacc produces C instead of a compiled object (.o) file. This is the most flexible arrangement—the generated code is portable and amenable to other processing whenever someone has a good idea.

yacc itself is a powerful tool. It takes some effort to learn, but the effort is repaid many times over. yacc-generated parsers are small, efficient, and correct (though the semantic actions are your own responsibility); many nasty parsing problems are taken care of automatically. Language-recognizing programs are easy to build, and (probably more important) can be modified repeatedly as the language definition evolves.

Stage 1 program. The source code for hoc1 consists of a grammar with actions, a lexical routine yylex, and a main, all in one file hoc.y. (yacc filenames traditionally end in .y, but this convention is not enforced by yacc itself, unlike cc with .c files) The grammar part is the first half of hoc.y:

```
%{
#include <stdio.h>        includes needed for code later on
#include <ctype.h>
#define YYSTYPE double    /* data type of yacc stack */
%}
```

```
%token  NUMBER
%left   '+' '-'   /* left associative, same precedence */
%left   '*' '/'   /* left associative, higher precedence */
%%
list:     /* nothing */
        | list '\n'
        | list expr '\n'  { printf("\t%.8g\n", $2); }
        ;
expr:     NUMBER          { $$ = $1; }
        | expr '+' expr   { $$ = $1 + $3; }
        | expr '-' expr   { $$ = $1 - $3; }
        | expr '*' expr   { $$ = $1 * $3; }
        | expr '/' expr   { $$ = $1 / $3; }
        | '(' expr ')'    { $$ = $2; }
        ;
%%
        /* end of grammar */
...
```

There's a lot of new information packed into these few lines. We are not going to explain all of it, and certainly not how the parser works—for that, you will have to read the `yacc` manual.

Alternate rules are separated by '`|`'. Any grammar rule can have an associated action, which will be performed when an instance of that rule is recognized in the input. An action is a sequence of C statements enclosed in braces `{` and `}`. Within an action, `$`n (that is, `$1`, `$2`, etc.) refers to the value returned by the nth component of the rule, and `$$` is the value to be returned as the value of the whole rule. So for example, in the rule

```
expr:  NUMBER  { $$ = $1; }
```

`$1` is the value returned by recognizing `NUMBER`; that value is to be returned as the value of the `expr`. The particular assignment `$$=$1` can be omitted—`$$` is always set to `$1` unless you explicitly set it to something else.

At the next level, when the rule is

```
expr:  expr '+' expr  { $$ = $1 + $3; }
```

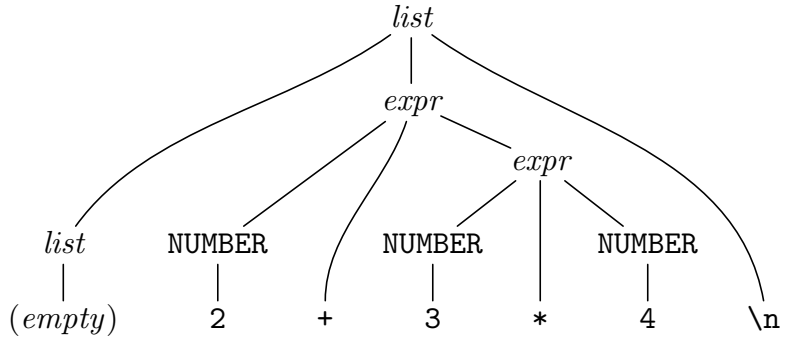
the value of the result `expr` is the sum of the values from the two component `expr`'s. Notice that `'+'` is `$2`; every component is numbered.

At the level above this, an expressoin followed by a newline `'\n'` is recognized as a list and its value is printed. If the end of the input follows such a construction, the parsing process terminates cleanly. A `list` can be an empty string; this is how blank input lines are handled.

`yacc` input is free form; our format is the recommended standard.

In this implementation, the act of recognizing or parsing the input also causes immediate evaluation of the expression. In more complicated situations (including `hoc4` and its successors), the parsing process generates code for later execution.

You may find it helpful to visualize parsing as drawing a *parse tree* like the one in the figure, and to imaginge values being computed and propagated up the tree from the leaves towards the root.



Parse Tree for `2 + 3 * 4`

The values of incompletely-recognized rules are actually kept on a stack; this is how the values are passed from one rule to the next. The data type of this stack is normally an `int`, but since we are processing floating point numbers, we have to override the default. The definition

```
#define YYSTYPE double
```

sets the stack type to `double`.

Syntactic classes that will be recognized by the lexical analyzer have to be declared unless they are single character literals like `+` and `-`. The declaration `%token` declares one or more such objects. Left or right associativity can be specified if appropriate by using `%left` or `%right` instead of `%token`. (Left associativity means that `a-b-c` will be parsed as `(a-b)-c` instead of `a-(b-c)`.) Precedence is determined by order of appearance: tokens in the same declaration are at the same level of precedence; tokens declared later are of higher precedence. In this way the grammar proper is ambiguous (that is, there are multiple ways to parse some inputs), but the extra information in the declarations resolves the ambiguity.

The rest of the code is the routines in the second half of the file `hoc.y`:

Continuing `hoc.y`

```
char    *progname;      /* for error messages */
int     lineno = 1;

int main(int argc, char *argv[])   /* hoc1 */
{
        progname = argv[0];
        yyparse();
        return 0;
}
```

`main` calls `yyparse` to parse the input. Looping from one expression to the next is done entirely within the grammar, by the sequence of productions for `list`. It would have been equally acceptable to put a loop around the call to `yyparse` in `main` and have the action for `list` print the value and return immediately.

yyparse in turn calls yylex repeatedly for input tokens. Our yylex is easy: it skips blanks and tabs, converts strings of digits into a numeric value, counts input lines for error reporting, and returns any other character as itself. Since the grammar expects to see only +, -, *, /, (,), and \n, any other character will cause yyparse to report an error. Returning a 0 signals "end of file" to yyparse.

Continuing hoc.y

```
int yylex(void)          /* hoc1 */
{
        int c;

        while ((c=getchar()) == ' ' || c == '\t')
                ;
        if (c == EOF)
                return 0;
        if (c == '.' || isdigit(c)) {   /* number */
                ungetc(c, stdin);
                scanf("%lf", &yylval);
                return NUMBER;
        }
        if (c == '\n')
                lineno++;
        return c;
}
```

The variable yylval is used for communication between the parser and the lexical analyzer; it is defined by yyparse, and has the same type as the yacc stack. yylex returns the *type* of a token as its function value, and sets yylval to the *value* of the token (if there is one). For instance, a floating point number has the type NUMBER and a value like 12.34. For some tokens, especially single characters like '+' and '\n', the grammar does not use the value, only the type. In that case, yylval need not be set.

The yacc declaration %token NUMBER is converted into a #define statement in the yacc output file y.tab.c, so NUMBER can be used as a constant anywhere in the C program. yacc chooses values that won't collide with ASCII characters.

If there is a syntax error, yyparse calls yyerror with a string containing the cryptic message "syntax error." The yacc user is expected to provide a yyerror; ours just passes the string on to another function, warning, which prints somewhat more information. Later versions of hoc will make direct use of warning.

```
void yyerror(char *s)  /* called for yacc syntax error */
{
        warning(s, (char *) 0);
}

void warning(char *s, char *t)  /* print warning message */
```

```
{
        fprintf(stderr, "%s: %s", progname, s);
        if (t)
                fprintf(stderr, " %s", t);
        fprintf(stderr, " near line %d\n", lineno);
}
```

This marks the end of the routines in `hoc.y`.

Compilation of a `yacc` program is a two-step process:

```
$ yacc hoc.y              Leaves output in  y.tab.c
$ cc y.tab.c -o hoc1      Leaves executable program in  hoc1
$ hoc1
2/3
        0.66666667
-3-4
hoc1: syntax error near line 1
$
```

Exercise 8-1. Examine the structure of the `y.tab.c` file. □

Making changes—unary minus. We claimed earlier that using `yacc` makes it easy to change a language. As an illustration, let's add unary minus to `hoc1`, so that expressions like

```
-3-4
```

are evaluated, not rejected as syntax errors.

Exactly two lines have to be added to `hoc.y`. A new token `UNARYMINUS` is added to the end of the precedence section, to make unary minus have highest precedence:

```
%left  '+' '-'
%left  '*' '/'
%left  UNARYMINUS      /* new */
```

The grammar is augmented with one more production for `expr`:

```
expr:    NUMBER                        { $$ = $1; }
       | '-' expr  %prec UNARYMINUS    { $$ = -$2; }  /* new */
```

The `%prec` says that a unary minus sign (that is, a minus sign before an expression) has the precedence of `UNARYMINUS` (high); the action is to change the sign. A minus sign between two expressions takes the default precedence.

Exercise 8-2. Add the operators `%` (modulus or remainder) and unary `+` to `hoc1`. Suggestion: look at `frexp`(3) [or rather `fmod`(3)]. □

A digression on `make`. It's a nuisance to have to type two commands to compile a new version of `hoc1`. Although it's certainly easy to make a shell file that does the job, there's a better way, one that will generalize nicely later on when there is more than one source file in the program. The program `make` reads a specification of how the components of a program depend on each other, and how to process them to create an up-to-date version of the program. It checks the times at which the various components were last modified, figures out the minimum amount of recompilation that has to be done to make a consistent new version, then runs the processes. `make` also understands the intricacies of multi-step processes like `yacc`, so these tasks can be put into a `make` specification without spelling out the individual steps.

`make` is most useful when the program being created is large enough to be spread over several source files, but it's handy even for something as small as `hoc1`. Here is the `make` specification for `hoc1`, which `make` expects in a file called `Makefile` or `makefile`.

```
CFLAGS=-std=c89 -Wall -Wextra

hoc1: hoc.o
        $(CC) $(LDFLAGS) hoc.o -o hoc1
```

The second line is indented with a tab, not with blanks! This makefile says that `hoc1` depends on `hoc.o`, and that `hoc.o` is converted into `hoc1` by running the C compiler and putting the output in `hoc1`. `make` already knows how to convert the `yacc` source file in `hoc.y` to an object file `hoc.o`:

```
$ make                  Make the first thing in Makefile, hoc1
yacc hoc.y
cc -c y.tab.c
rm y.tab.c
mv y.tab.o hoc.o
cc hoc.o -o hoc1
$ make                  Do it again
'hoc1' is up to date.   make realizes it's unnecessary
$
```

Stage 2: Variables and error recovery

The next step (a small one) is to add "memory" to `hoc1`, to make `hoc2`. The memory has 26 variables, named `a` to `z`. This isn't very elegant, but it's an easy and useful intermediate step. We'll also add some error handling. If you try `hoc1`, you'll recognize that its approach to syntax errors is to print a message and die, and its treatment of arithmetic errors like division by zero is reprehensible:

```
$ hoc1
1/0
Floating exception - core dumped
$
```

The changes needed for these new features are modest, about 35 lines of code. The lexical analyzer `yylex` has to recognize letters as variables; the grammar has to include productions of the form

```
expr:   VAR
      | VAR '=' expr
```

An expression can contain an assignment, which permits multiple assignments like

```
x = y = z = 0
```

The easiest way to store the values of the variables is in a 26-element array; the single-letter variable name can be used to index the array. But if the grammar is to process both variable names and values in the same stack, `yacc` has to be told that its stack contains a union of a `double` and an `int`, not just a `double`. This is done with the `%union` declaration near the top. A `#define` or a `typedef` is fine for setting the stack to a basic type like `double`, but the `%union` mechanism is required for union types because `yacc` checks for consistency in expressions like `$$=$2`.

Here is the grammar part of `hoc.y` for `hoc2`:

```
%{
double mem[26];          /* memory for variables 'a' to 'z' */
%}
%union {
        double  val;     /* actual value */
        int     index;   /* index into mem[] */
}
%token  <val>   NUMBER
%token  <index> VAR      /* VAR is index member of union */
%type   <val>   expr     /* expr is val member of union */
%right  '='
%left   '+' '-'
%left   '*' '/'
%left   UNARYPM
%%
left:     /* nothing */
        | list '\n'
        | list expr '\n'      { printf("\t%.8g\n", $2); }
        | list error '\n'     { yyerrok; }
        ;
```

```
expr:     NUMBER
        | VAR             { $$ = mem[$1]; }
        | VAR '=' expr    { $$ = mem[$1] = $3; }
        | expr '+' expr   { $$ = $1 + $3; }
        | expr '-' expr   { $$ = $1 - $3; }
        | expr '*' expr   { $$ = $1 * $3; }
        | expr '/' expr   { if ($3 == 0.0)
                              execerror("division by zero", "");
                            $$ = $1 / $3; }
        | '(' expr ')'    { $$ = $2; }
        | '-' expr  %prec UNARYPM  { $$ = -$2; }
        ;
%%
        /* end of grammar */
...
```

The `%union` says that stack elements hold either a `double` (a number, the usual case), or an `int`, which is an index into the array `mem`. The `%token` declarations have been augmented with a type indicator. The `%type` declaration specifies that `expr` is the `<val>` member of the union, i.e., a `double`. The type information makes it possible for `yacc` to generate references to the corect members of the union. Notice also that `=` is right-associative, while the other operators are left-associative.

Error handling comes in several pieces. The obvious one is a test for a zero divisor; if one occurs, an error routine `execerror` is called.

A second test is to catch the "floating point exception" signal that occurs when a floating point number overflows. The signal is set in `main`.

The final part of error recovery is the addition of a production for `error`. "`error`" is a reserved word in a `yacc` grammar; it provides a way to anticipate and recover from a syntax error. If an error occurs, `yacc` will eventually try to use this production, recognize the error as grammatically "correct," and thus recover. The action `yyerrok` sets a flag in the parser that permits it to get back into a sensible parsing state. Error recovery is difficult in any parser; you should be aware that we have taken only the most elementary steps here, and have skipped rapidly over `yacc`'s capabilities as well.

The actions in the `hoc2` grammar are not much changed. Here is `main`, to which we have added `setjmp` to save a clean state suitable for resuming after an error. `execerror` does the matching `longjmp`.

```
...
#include <signal.h>
#include <setjmp.h>
jmp_buf begin;

int main(int argc, char *argv[])  /* hoc2 */
{
        int fpecatch(void);
```

```
        progname = argv[0];
        setjmp(begin);
        signal(SIGFPE, fpecatch);
        yyparse();
        return 0;
}

void execerror(char *s, char *t)  /* run-time error recovery */
{
        warning(s, t);
        longjmp(begin, 0);
}

void fpecatch(int signum)  /* catch floating point exceptions */
{
        execerror("floating point exception", (char *) 0);
}
```

For debugging, we found it convenient to have `execerror` call `abort`(3), which causes a core dump that can be perused with `adb` or `sdb` [or `gdb`]. Once the program is fairly robust, `abort` is replaced by `longjmp`.

The lexical analyzer is a little different from `hoc2`. There is an extra test for a lower-case letter, and since `yylval` is now a union, the proper member has to be set before `yylex` returns. Here are the parts that have changed:

```
int yylex(void)  /* hoc2 */
...
        if (c == '.' || isdigit(c)) {  /* number */
                ungetc(c, stdin);
                scanf("%lf", &yylval.val);
                return NUMBER;
        }
        if (islower(c)) {
                yylval.index = c - 'a';  /* ASCII only */
                return VAR;
        }
...
```

Again, notice how the token type (e.g., `NUMBER`) is distinct from its value (e.g., 3.1416);

Let us illustrate variables and error recovery, the new things in `hoc2`:

```
$ hoc2
x = 355
        355
y = 113
        113
```

```
p = x/z                              z is undefined and thus zero
hoc2: division by zero near line 4       Error recovery
x/y
        3.1415929
1e30 * 1e30                              Overflow
hoc2: floating point exception near line 5
...
```

Actually, the PDP-11 requires special arrangements to detect floating point overflow, but on most other machines `hoc2` behaves as shown.

Exercise 8-3. Add a facility for remembering the most recent value computed, so that it does not have to be retyped in a sequence of related computations. One solution is to make it one of the variables, for instance '`p`' for 'previous.' □

Exercise 8-4. Modify `hoc` so that a semicolon can be used as an expression terminator equivalent to a newline. □
